The Efficiency of Non-Contrast Computed Tomography in the Estimation of Urinary Stone Composition

Ilker Atici¹, Nuray Voyvoda²,³, Ozlem Tokgoz¹, Husnu Tokgoz²

Abstract

**Background:** Prior knowledge of stone composition is key to determining stone brittleness as well as treatment management and prophylactic approach. The present study seeks to visualize stone type on non-contrast computed tomography on the basis of Hounsfield Unit (HU) values.

**Methods:** A retrospective evaluation was performed of non-contrast computed tomography scans of patients who underwent urinary system operation to remove stones which were subjected to biochemical analysis. The localization and size of the stones were determined and their HU values, mean attenuation/size (HUD) and maximum attenuation/size ratios were calculated.

**Results:** The results of stone analysis revealed 34 calcium phosphate, 11 calcium oxalate, 5 triple phosphate (struvite) stones. On the basis of measurement results, a significant difference was identified among HU values of the three stone types (P = 0.002). When the stones were compared in pairs, this difference was established to be due to the difference between the densities of calcium phosphate and struvite stones. No significant difference was observed among the stone groups with regard to HUD and maximum attenuation/size ratios.

**Conclusions:** HU values are a useful parameter to distinguish between calcium phosphate and struvite stones. The inclusion of HU values in reports will set the right course for treatment.

**Keywords:** Kidney stone; Computed tomography; Analysis

Introduction

The most significant recent advance in the imaging of renal calculi has been the development of non-contrast computed tomography (NCCT) and its use in the detection of ureteral and renal stones [1]. The speed, safety and accuracy of NCCT make it the method of choice in the assessment of patients with suspected urinary tract calculi [2-9].

Compared with plain radiography, ultrasound and intravenous urography, NCCT is superior in its ability to detect urinary calculi, to distinguish calculi from other abnormalities (e.g. blood clot, stricture or neoplasm) and to identify non-urological causes of flank pain. The ability of NCCT to assess stone size and location is well accepted, but less clear is its ability to determine stone composition [10].

Knowing the composition of a urinary calculus is frequently a key factor in determining its most appropriate management. The selection of the optimal treatment method (e.g. ureteroscopy, pyelolithotomy, percutaneous lithotripsy or extracorporeal shock wave lithotripsy) depends primarily on the chemical composition of the individual patient’s calculus is essential. It is conceivable that the ability to predict stone composition before treatment would enable the urologist to group patients according to stone density and treat them accordingly. Thus, those patients with high density stones could be managed endoscopically rather than by ESWL, since stones composed of calcium oxalate monohydrate and cystine typically do not fragment well with ESWL [11].

While blood chemistries, examination of the urine sediment, and review of the patient’s clinical history are helpful, the true nature of a calculus often remains in doubt [12]. To date, although several in vitro studies have investigated
whether NCCT could determine the chemical composition of urinary calculi, few in vivo studies have been performed. Hence, this study was undertaken to see if an in vivo Hounsfield Unit (HU) or HU density measurement could be used to predict the composition of urinary stones.

Materials and Methods

Of the patients who were admitted to our hospital between 2005 and 2010, those with suspected urinary tract stone disease were identified on the basis of prior stone history, physical examination and laboratory findings. The patients were included for study who were confirmed to have stones in the urinary system based on NCCT and whose stones were removed by operation and subjected to chemical analysis. Those patients with urinary tract catheters who were given contrast material intravenously or orally and underwent postoperative tomography were excluded from the study.

In addition, those cases were excluded from the study in which the number of cystine and calcium carbonate stones identified was not sufficient enough to achieve a significant overlap. The local ethics committee approved the study.

CT protocol

The CT scans were obtained by means of a Philips Secure Spiral CT scanner and a Toshiba Activion 16 CT scanner. The scans were performed by using a standard stone viewing protocol at 120 - 140 kV, 79 - 260 mA, a section in the 3 - 5 mm range and a section thickness of 3 - 5 mm.

Image analysis

The image analysis of each scan was carried out in two separate evaluating sessions by two staff radiologists (IA, NV) unaware of stone composition.

The radiologist who performed the assessment detected stones on the existing scans which were then removed by surgery. For each calculus, a region of interest was created overlying the whole calculus on the slice in which it was seen at its largest diameter.

The window width (WW) was adjusted to 2500 and the window level (WL) to 480. The slice was magnified four fold, three different points were determined where the stone was observed to be the densest and the Hounsfield unit was measured of an area 1 mm on average. On the basis of these results, the mean HU value was recorded.

Hounsfield unit density (HUD) was also calculated for each stone by taking the mean HU for each stone and dividing it by the largest transverse diameter of the stone.

Next, the peak attenuation for the stones and the peak attenuation/size ratio were compared with the results of the stone analysis.

Statistical analysis

The statistical evaluation was conducted by means of SPSS (version 13.0). How well numerical variables fit a normal distribution was visualized using the Kolmogorov-Smirnov test. The definitive statistics for numerical variables were expressed in average ± standard deviation and those for categorical data in numbers and percentages. The differences between groups with regard to categorical variables and the relationships between variables were studied by means of Chi-square test. The assessment of the differences between the two measurements was undertaken by the paired t-test. One-way analysis of variance was employed in comparing the 3 stone types in terms of numerical variables that displayed normal distribution. A 95% confidence interval was obtained when evaluating the results. Results were considered significant when P < 0.05.

Results

The study population was a total of 50 patients, 39 men and 11 women ranging in age from 24 to 8, whose average age was 50.

The patients were admitted to our hospital with side pains or dysuria, 16 of the patients had one or more additional systemic diseases (14 had hypertension, 2 chronic renal insufficiency, 4 diabetes mellitus, 2 congestive cardiac insufficiency, 1 chronic obstructive pulmonary disease). One patient was receiving treatment for hypercalcemia.

The stone sizes ranged from minimum 5 mm to maximum 50 mm (mean 2 cm), 22 of the stones were located in the right urinary system (15 in the kidney and 7 in the ureter) and 28 in the left urinary system (22 in the kidney and 6 in the ureter).

Stone analysis carried out revealed 34 calcium phosphate, 11 calcium oxalate and 5 struvite stones.
A comparison of the stone types with regard to age identified a significant difference between them (P = 0.024). This was found to be due to difference between the average age of the patients with struvite stones and that of the patients with calcium oxalate stones (Table 1).

No significant difference was noted when the stones were compared with regard to gender (P = 0.620) (Table 2).

The difference between the HU values of the 3 stone groups on the basis of, the measurements by the first and second observers was found to be significant (P = 0.002 and P = 0.003) (Table 3).

It was discovered that this difference was caused by the difference between the HU values for phosphate stones and those for struvite stones (P = 0.003 and P = 0.004, respectively). The difference among HU values for calcium phosphate-calcium oxalate and calcium oxalate-struvite stones was found not to be significant.

For two observers, when HUD was compared with regard to stone types no significant difference was observed among them (P = 0.135 and P = 1.159) (Table 3). When the ratio of the maximum stone density to stone size was compared with regard to stone type, no significance was observed among the stone types (P = 0.137 and P = 0.194) (Table 3).

The measurements conducted by the two observers were statistically significant (P = 0.981).

Given a cut-off value which was assumed to be 80 for HUD, 8 CaP, 2 CaO and 1 struvite stones were found which had a HUD greater than 80, and 26 CaP, 9 CaO and 4 struvite stones were identified whose HUD was less than 80 (Table 4).

### Discussion

The choice of effective clinical management of urinary tract calculi can be facilitated by knowing the precise chemical composition of the stones and their corresponding fragility [13, 14].

Indeed, predicting susceptibility to fragmentation in situ before treatment, notably extracorporeal shock wave lithotripsy and endoscopic laser lithotripsy, could be potentially useful [15]. Knowing the composition of these stones can also be useful for patients who are susceptible to dietary management or metabolic intervention [16].

Typically, pure stones composed of calcium oxalate monohydrate and brushite or cystine are relatively refractory to shock wave lithotripsy and percutaneous ultrasonic lithotripsy, and are more likely to be treated endoscopically whereas uric acid stones are usually treated with oral alka-
linization [13, 14, 17, 18]. Calcium oxalate dihydrate and struvite stones usually fragment easily with both shock wave lithotripsy and ultrasonic lithotripsy [16].

NCCT has emerged as the modality of choice in the evaluation of acute flank pain. The basic advantages of NCCT over other imaging methods include high sensitivity and specificity in the detection of ureteral and renal stones, speed, safety, detection of nonurological pathology and cost [19].

Contradictory findings have been published in the literature regarding the ability of helical CT to accurately assess the chemical composition of renal calculi [16]. These variations can be explained by the use of the different CT scanners, degree of collimation, energy setting, technique, stone size and perhaps interpretation of CT numbers [19].

The technique of CT scanning plays a role in measuring the HU values of urinary stones, specifically the size of col-
limation [20]. Saw et al. found that scanning stones that were smaller than the size of collimation subjected them to partial volume inaccuracies which had an impact on the measured HU values. They concluded that using a smaller collimation size permitted better accuracy in the prediction of stone composition [20]. Another parameter in the CT technique is dual energy scanning in which the differences in radiodensity observed by scanning stones at different energies are used for determination of their compositions [21, 22].

In our study, NCCT was performed with a collimation of 3 - 5 mm using single-energy scanning at 120 - 140 kV. The use of 1 mm collimation is clinically impractical in the routine evaluation of acute flank pain. Dual-kilovolt scanning also is not practical, and requires repeated imaging of the patient [23]. As we did not use stones less than 5 mm in our study, the partial volume effect due to collimation was minimalized.

The studies which Motley et al. carried out on 100 pa-
tients revealed that 87 patients had calcium stones, 7 uric acid stones, 4 struvite stones and 2 cystine stones. Their HU values were found to be 440 ± 262, 270 ± 134, 401 ± 198, 248 ± 0 respectively. They did not find a significant differ-
ence between the average HU values for these stone types [24].

Demirel et al., in their studies performed on 87 patients, discovered that 54 patients had calcium oxalate stones, 19 struvite stones and 14 uric acid stones, whose HU values were 812 ± 135, 614 ± 121 and 413 ± 143, respectively [19]. It was possible to distinguish between these three types of stones on the basis of their average HU values (P = 0.001).

Patel et al. conducted an analysis of 100 stones and found that 56 of them contained calcium oxalate monohy-
drator (CaOMH), 16 calcium oxalate dihydrate (CaODH), 4 brushite, 9 apatite, 2 cystine and 13 uric acid. Based on their HU values, the calcium phosphate stones (brushite and apatite) are stones with the highest density just as our study demonstrated (1123 ± 254 and 844 ± 346). In the present study, HU values for CaOMH, CaODH, cystine and uric acid were established to be 879 ± 230, 517 ± 205, 550 ± 74 and 338 ± 145, respectively. The HU values of the calcium stones were found to display significant difference with regard to their subtypes [25].

Our studies revealed that calcium phosphate stones had a HU value of 1080 ± 410, calcium oxalate stones 849 ± 348 and struvite stones 446 ± 191. It was demonstrated that calcium phosphate and struvite stones can be distinguished on the basis of their HU values.

Motley et al. postulated that as stone size increases, so does the HU value and put forward the concept of Hounsfield unit density (HU/stone size) to eliminate the effect of stone size. They found HU values to be 105 ± 43 for calcium stones and 53 ± 28 for struvite stones, and reported that cal-
cium stones could be distinguished from calcium-free ones [24]. However, our study clearly shows that HU values do not make it possible to make a distinction among CaP, CaO and struvite stones.

Nakada et al and Motley et al. argue that uric acid and CaO stones can be distinguished by assuming the cutoff val-

HUD: Hounsfield Unit Density; cutoff value: 80.
ue to be 80 [24, 26]. In contrast, a cutoff value of 80 assumed for our study failed to enable distinction between CaO, CaP, or struvite stones based on HUD.

During our study, when the ratio- of the maximum stone density to stone size was compared with regard to stone type, no significance was observed among the stone types.

In this and other in vivo studies, the densities of all the stone types were lower than those reported in in vitro studies [20-22, 24, 26]. As defined by Nakada et al., this is probably because of a volume-averaging effect from the surrounding soft tissues and the use of a smaller collimation size in in vitro studies [26].

In conclusion, NNCT in a patient who presents with acute flank pain provides information on stone size and localization as well as its content. Knowledge of hounsfield values of stones and their appearance in reports can determine the course of treatment.

The facts that calcium stones were not analyzed on the basis of their subtypes and not all stone types were identified during our study are our limitations. Larger clinical studies are required to assess this procedure further.
